Case Report

Hypopituitarism Associated with Cogan's Syndrome; High-dose Glucocorticoid Therapy Reverses Pituitary Swelling

Masanori KANATANI, Ryohji NAKAMURA, Keizo KUROKAWA, Masahiko TAODA, Yoko NEMOTO, Keiko KAMAKURA, Nobuo KUGAI, Naokazu NAGATA, Osamu TAKATANI and Kazuhiro TSUCHIYA*

A 70-year-old woman with Cogan's syndrome first presented with central diabetes insipidus and then developed secondary hypothyroidism. Magnetic resonance imaging revealed a diffuse pituitary swelling without evidence of tumor. High-dose glucocorticoid therapy administered to treat Cogan's syndrome was very effective in suppressing the inflammatory process, and resulted in the reversal of the pituitary swelling and partial recovery of thyroid stimulating hormone secretion. This is the first case of hypopituitarism associated with Cogan's syndrome, a form of autoimmune vasculitis. The glucocorticoid-responsive pituitary lesion is best explained by autoimmune hypophyisis which shows pituitary swelling and is known to often associate with other autoimmune phenomena.

Key words: Lymphocytic hypophyisis, Central diabetes insipidus, Magnetic resonance imaging, Pituitary swelling

Cogan's syndrome is a rare clinical entity characterized by non-syphilitic interstitial keratitis with vestibulocauditory dysfunction (1). The pathogenesis of this syndrome is now considered to be systemic vasculitis, and there are many case reports associated with additional clinical problems such as heart, musculoskeletal, nerve and lymph node involvement (2, 3). However, none of the patients with Cogan's syndrome has been reported to manifest endocrinopathy. Herein we report the first case of Cogan's syndrome with an accompanying pituitary lesion resulting in central diabetes insipidus and secondary hypothyroidism. Magnetic resonance imaging (MRI) revealed a diffuse pituitary swelling which was reversed after a high-dose glucocorticoid therapy.

CASE REPORT

A 70-year-old woman was admitted to our hospital on January 24, 1989 because of headache, polyuria and polydipsia. She was well until 4 months before the admission when she began to experience headache along with vertigo and hyperemia of the left bulbar conjunctiva. A month before admission she noticed the abrupt onset of polydipsia and polyuria. She had experienced three uneventful deliveries. Her menopause was at the age of 50. There was a history of mild hypertension for the last two yr.

Examination on admission revealed a moderately obese woman whose wt was 53 kg and ht 143 cm. Her body temperature was 37.3°C, pulse 104/min and blood pressure 160/100 mmHg. The tongue was...
Hypopituitarism and Cogan's Syndrome

dry. The left bulbar conjunctiva was hyperemic and
was diagnosed as scleritis. The thyroid gland was
not palpable. Optic fundi and the visual fields were
normal. Neurological examination was negative
except for nystagmus and left hearing loss confirmed
by electroneystagmography and audiogram,
respectively. Urine gave a normal urinalysis with a
specific gravity of 1010. The hemoglobin
concentration was 14.9 g/dl with a normochromic
normocytic film; the white cell count was
13,200/mm³ with 7% band forms, 59% segmented
neutrophils, 28% lymphocytes and 6% monocytes;
the platelet count was 401,000/mm³. The
erthrocyte sedimentation rate (ESR) was 49 mm/h
and C-reactive protein (CRP) was 0.4 mg/dl. The
serum level of Na was 147 mEq/l, K 4.1 mEq/l, Cl
107 mEq/l, Ca 8.6 mg/dl and P 4.3 mg/dl. The
serum glucose level was 99 mg/dl and urea nitrogen
16 mg/dl. The plasma osmolality was 290 mOsm/Kg
• H₂O and that of urine was 121 mOsm/Kg • H₂O.
Serum angiotensin converting enzyme activity was
15.4 U/ml. Antinuclear antibodies were negative and
CH₅₀ was 48.4 U/ml. Anti-microsomal and anti-
thyroglobulin antibodies were positive at titers of
1:400 and 1:400, respectively, but antipituitary
antibodies reacting against plasma membrane of
ACTH and GH cells or cytoplasm of rat pituitary
cells were all negative (Biomedical Laboratories,
Kawagoe, Saitama). Tuberculin skin test was
positive. X-ray studies of the chest and skull were
unremarkable.

During 8 h of water deprivation, the plasma
osmolality increased from 295 to 301 mOsm/Kg •
H₂O, those of urine from 104 to 412 mOsm/Kg •
H₂O, and serum antidiuretic hormone (ADH) from
1.0 to 1.2 pg/ml. After vasopressin injection, urine
osmolality was 466 mOsm/Kg • H₂O at 60 min.
Central partial diabetes insipidus was diagnosed and
nasal desamino-8-D-arginine vasopressin (DDAVP)
treatment successfully controlled urine volume.

The plasma levels of free triiodothyronine (T₃)
was 2.9 pg/ml, free thyroxin (T₄) 1.23 ng/dl, cortisol 17.8 µg/dl and estradiol 49.8 pg/ml. The
anterior pituitary function was fairly well preserved
(Table 1). Computed tomographic (CT) scan and
MRI (Fig. 1A) showed diffuse homogenous swelling
of the pituitary extending to its stalk. On MRI, no
difference in intensity could be discerned between
anterior and posterior lobes. Surgical exploration of
the pituitary was not performed because the
possibility of a pituitary tumor was low, and she was
discharged on 15 µg/day of DDAVP.

Severe headache continued, and she was re-
admitted a month later. Shortly before the readmis-
sion, she began to feel cold intolerance and her
serum levels of free T₄ and thyroid-stimulating
hormone (TSH), both basal and stimulated, were
low (Fig. 2 and Table 1). Levels of gonadotropins,
both basal and luteinizing hormone (LH)-releasing
hormone (LHRH) stimulated, were also lower than
those observed during the first admission; moderate
hyperprolactinemia was also noted (Table 1). Plasma
level of cortisol was 16 µg/dl in the morning.

The cold intolerance disappeared by the replace-

Fig. 2. Clinical course. As the symptoms of Cogan's syndrome became exacerbated, secondary hypothyroidism progressed gradually. Prednisolone therapy improved not only the symptoms of Cogan's syndrome but also the basal and TRH-stimulated levels of serum TSH.

Polydipsia - Polyuria
Facial Nerve Palsy
Tinnitus - Scleritis - Headache

Patients with Cogan's syndrome typically present with uveitis, keratitis, hearing loss, and neurologic involvement. In this case, the patient exhibited signs of hypo- and hyperthyroidism, which are common complications in Cogan's syndrome. The patient's symptoms improved after the initiation of prednisolone therapy, highlighting the importance of early intervention in managing the disease.

In addition to his clinical presentation, laboratory tests revealed a white blood cell count of 14,300/mm³, ESR 94 mm/h and CRP 16.0 mg/dl, and a spinal tap revealed that the cell count of cerebrospinal fluid (CSF) was 50/3 with 22% neutrophils and 78% lymphocytes, glucose 56 mg/dl, and protein 38 mg/dl with negative microbiological study. Vasculitis was demonstrated histopathologically in a specimen obtained from biceps muscle.

Stubborn headache, vestibuloaditory dysfunction, scleritis, aseptic meningitis, parotid swelling, facial nerve palsy and persistent positive infrace.
matory indices were all compatible with Cogan's syndrome, and 60 mg/day of prednisolone was started. As shown in Fig. 2, the headache, parotid swelling and scleritis disappeared within several days, and ESR, CRP and CSF findings also were normalized. CT scan and MRI obtained two wk after the initiation of prednisolone therapy demonstrated the resolution of pituitary swelling (Fig. 1B). The reassessment of pituitary function when the dose of prednisolone was tapered to 30 mg/day revealed an increase in the basal level of TSH as well as a partial improvement of TSH response to TRH, and a normalization of basal prolactin (PRL) (Fig. 2 and Table 1). There were no remarkable changes in basal and stimulated levels of gonadotropins (Table 1), and a trial to withdraw DDAVP was not successful. Six months after the initiation of prednisolone she is well without any signs or symptoms of inflammation and is on 25 mg/day of prednisolone.

**DISCUSSION**

The case presented here appears to be the first case of hypopituitarism associated with Cogan's syndrome. MRI clearly demonstrated a response of a presumed inflammatory pituitary lesion to high-dose glucocorticoid.

Non-sympathetic interstitial keratitis with vestibuloauditory dysfunction was first described by Mogan and Baumgartner (4) in 1934, and was established as a clinical entity by Cogan (1) in 1945. Generally, Cogan's syndrome is diagnosed from variable ophthalmic lesions including the scleritis, auditory and vestibular symptoms and laboratory findings including mild to moderate leukocytosis, elevated ESR, positive CRP, normal complement levels and negative antinuclear antibody titers. Although the pathological basis of the syndrome is proposed to be a systemic vasculitis resulting from allergic hypersensitivity or autoimmune mechanism, histopathological evidence has been demonstrated only in 12 cases among 119 cases reported. Of these cases with proven vasculitis, nine cases of periarteritis nodosa or necrotizing vasculitis (5–12), two cases of nodritis (13, 14) and a case with a lesion resembling Burger's disease (15) were reported.

In presentation, the present case had marked polyuria, directing our attention to search for pituitary dysfunction. However, ophthalmic and vestibuloauditory lesions, slight fever along with leukocytosis, elevated ESR and positive CRP had indicated the presence of an inflammatory process consistent with Cogan syndrome. Partial central diabetes insipidus was controlled by nasal DDAVP administration, but secondary hypothyroidism developed concomitantly with exacerbation of Cogan's syndrome, as indicated by the advent of left facial nerve palsy, parotitis, septic meningitis and further increment in CRP value. In accordance with the notion that Cogan syndrome is a systemic disease arising from vasculitis, there are many reports of cases with additional clinical manifestations beyond the original description (2, 3). Although no case of Cogan syndrome has been reported to accompany hypothalamic-pituitary dysfunction, the clinical features observed in this patient are best explained by the possibility of Cogan's syndrome causing the hypothalamic-pituitary dysfunction as an unusual associated clinical presentation. Central diabetes insipidus along with hyperprolactinemia suggests that the lesion extended from the pituitary stalk to the hypothalamus; the hypothyroidism with a lack of TSH response to TRH indicated damage to the pituitary itself.

Since no surgical procedure was performed, the pathological process leading to the pituitary dysfunction in the present patient could not be elucidated conclusively. Temporal arteritis which is a subtype of a vasculitis syndrome like Cogan's syndrome included in the list of causes of hypopituitarism. The pathology of a pituitary lesion which was caused by temporal arteritis was reported to be ischemic (16), and the MRI appearance of our patient was not considered to be compatible with such an ischemic lesion.

The reversal of a diffuse swelling of the pituitary demonstrated by MRI after high-dose glucocorticoid therapy suggests the possible pituitary pathology of autoimmune-related lymphocytic or granulomatous giant cell hypophysitis, anecdotal lesions such as lymphoma, sarcoidosis, or eosinophilic granuloma. Lymphoma confined to hypophysis should be considered, but the absence of a mass effect to the surrounding structures along with benign CSF cytology renders the possibility of lymphoma to be low. The possibility of sarcoidosis is also low because
of the absence of hilar lymphadenopathy, normal serum angiotensin converting enzyme activity and the positive tuberculin skin test. Although rare cases with diabetes insipidus and hypopituitarism whose parasellar masses were proved to be an eosinophilic granuloma have been described (17, 18), it usually presents as an infiltrative lesion. Lytic lesions of other bones characteristic to eosinophilic granuloma were not observed in our patient. Therefore eosinophilic granuloma is also unlikely.

Accordingly, although only through the exclusion of several pathological states above mentioned, we considered it most probable that the inflammatory process around the pituitary in the present patient occurred from a common pathological process to Cogan’s syndrome, namely from an immunological process. Lymphocytic hypophysitis and giant cell granulomatous hypophysitis may be the representatives in this category. Although the lymphocytic hypophysitis has been often reported in young women in the peripartum period who developed hypopituitarism associated with a presumed pituitary tumor (19–23), giant cell granulomatous hypophysitis is seen primarily in middle aged or older women (24, 25). At present, the pathogenesis and interrelationship between these two entities are unknown, but an autoimmune inflammatory process is thought to be highly possible. Lymphocytic hypophysitis is often associated with other autoimmune phenomena (22), and the present patient had positive antithyroid antibodies and Cogan’s syndrome which is presumed to be an autoimmune vasculitis.

Finally, the change in the serum TSH level after glucocorticoid therapy is noteworthy. The basal level of TSH, once undetectable, became detectable, and its response to TRH also recovered. Although the recovery of TSH was minimal, it appears to be meaningful especially because it was measured while the patient was taking a pharmacological dose of glucocorticoid, which is known to exhibit suppressive effects on basal and TRH-stimulated TSH (26). This, along with the MRI study, may indicate the possibility that the treatment with a high-dose glucocorticoid may reverse, at least partially, not only the anatomical but also the functional derangement of some pituitary lesions possibly associated with an autoimmune mechanism as assumed in this case.
